Abstract

Adaptive radiation plays a fundamental role in our understanding of the evolutionary process. However, the concept has provoked strong and differing opinions concerning its definition and nature among researchers studying a wide diversity of systems. Here, we take a broad view of what constitutes an adaptive radiation, and seek to find commonalities among disparate examples, ranging

from plants to invertebrate and vertebrate animals, and remote islands to lakes and continents, to better understand processes shared across adaptive radiations. We surveyed many groups to evaluate factors considered important in a large variety of species radiations. In each of these studies, ecological opportunity of some form is identified as a prerequisite for adaptive radiation. However, evolvability, which can be enhanced by hybridization between distantly related species, may play a role in seeding entire radiations. Within radiations, the processes that lead to speciation depend largely on (1) whether the primary drivers of ecological shifts are (a) external to the membership of the radiation itself (mostly divergent or disruptive ecological selection) or (b) due to competition within the radiation membership (interactions among members) subsequent to reproductive isolation in similar environments, and (2) the extent and timing of admixture. These differences translate into different patterns of species accumulation and subsequent patterns of diversity across an adaptive radiation. Adaptive radiations occur in an extraordinary diversity of different ways, and continue to provide rich data for a better understanding of the diversification of life.

Background

Adaptive radiation has been considered the connector that unites ecology and evolution (Givnish and Sytsma 1997). Since capturing the attention of evolutionary biologists when Darwin, using the Galapagos finches, developed his “principle of divergence,” studies of adaptive radiation have been central in developing our understanding of the mechanisms that drive speciation, diversification, and many associated ecological and evolutionary processes (Simpson 1953; Givnish and Sytsma 1997; Schlüter 2000; Grant and Grant 2014). However, research on adaptive radiations is often as disparate as the ecologically differentiated species contained within them, which makes generalization of process and patterns across systems difficult. One of the few uniting commonalities is that adaptive radiations generally, though not always (Losos 2010), require ecological opportunity and are associated at some stage with divergent natural selection shaping adaptation to the biotic or abiotic environment (Schlüter 2000; Stroud and Losos 2016). Beyond this point, there has been limited consensus on what processes shape adaptive radiations across space, time, and taxa. The current paper arose from a meeting of the American Genetic Association held in Waimea, Hawaii, in July 2018 with the goal of synthesizing our knowledge of ecologically, geographically, and taxonomically diverse radiations (Figure 1) to provide a more general understanding of the diversity of processes that are included under the umbrella of adaptive radiation. We attempt to identify common denominators, where they exist, and to highlight differences, where we think they are real and important, that underlie adaptive radiations, to reinvigorate the search for general framework for explaining when—and how—they occur.

What Do We Mean by “Adaptive Radiation?”

The definition of adaptive radiation has been elusive, as the term has been used for a broad array of situations from the classically recognized rapid adaptive radiations of Galapagos finches and African Great Lakes cichlids, to the striking, but slow, radiations of Greater Antilles *Anolis* lizards, and *Bromelina* bromeliads in the South American tepuis (Givnish 2015), and from intraspecific divergence (Hendry et al. 2009) to ancient divergences among major lineages (Burns and Sidlauskas 2019). The term has also been used to describe species that are largely allopatric (Murray et al. 1993) and single species showing divergent feeding behavior (Knudsen et al. 2010), to much more diverse clades of insects (Bennett and O’Grady 2013; O’Grady and DeSalle 2018), and spiders that co-occur

syntopically within a given island (Gillespie 2016), as well as everything in between. Furthermore, debate over the distinction between adaptive and nonadaptive radiations continues (Czekanski-Moir and Rundell 2019), in particular, because (1) nonadaptive radiation (the formation of multiple species that are ecologically similar) can sometimes give way to classic adaptive radiation as newly formed species develop ecological differences in the course of diversification (Rundell and Price 2009); such ecological divergence can be tied to interactions with ecologically similar close relatives (see below). Alternatively, (2) ecological separation may be largely limited to divergences at the onset of the radiation, with subsequent speciation events over the course of the radiation occurring in isolation without major ecological shifts. Clearly, different processes are involved in adaptive radiation, adding to confusion in its use (Olson and Arroyo-Santos 2009).

Attempting to resolve problems inherent in the term, a number of authors have proposed new and improved definitions of adaptive radiation, as well as criteria for demonstrating when one has or has not occurred. Perhaps the most widely accepted definition currently is that proposed by Schlüter (2000)—the evolution of ecological diversity within a rapidly multiplying lineage; this is evaluated by a set of four criteria, (1) common ancestry, (2) phenotype-environment correlation, (3) trait utility, and (4) rapid speciation. It has proven exceptionally difficult, however, for most studies to satisfy all these criteria (Rundell and Price 2009). As a result, the number of cases that can be considered “adaptive radiations” under these criteria is relatively few. At the other extreme are definitions that are broadly inclusive. Such definitions include the ‘evolutionary divergence of members of a single monophyletic lineage into a variety of adaptive forms’ (Futuyma 1998; Losos 2010); a ‘pattern of species diversification in which different species within a lineage occupy a diversity of ecological roles, with associated adaptations’ (Gillespie et al. 2001); and the ‘rise of a diversity of ecological roles and associated adaptations within a lineage, accompanied by an unusually high level or rate of accumulation of morphological/physiological/behavioral disparity and ecological divergence’ (Givnish 2015). As an alternative to emphasizing a definition, other authors have sought to separate the different components of the phenomenon—treating rate separately from ecological and morphological disparity (Donoghue and Sanderson 2015; Salzburger 2018), or by dividing the phenomenon into various components, such as 1) multiplication of species of common descent, 2) adaptation via natural selection, and 3) extraordinary diversification; testing for each criterion separately (Glor 2010). Importantly, it is clear that adaptive radiation covers many

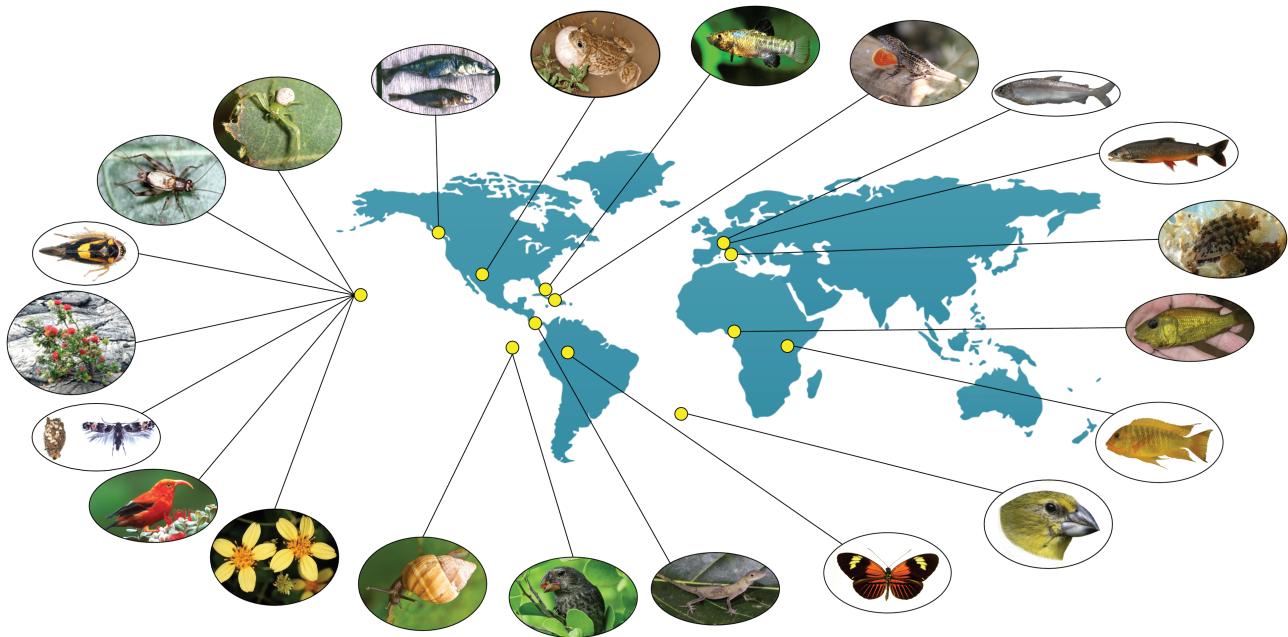

Figure 1. Model systems studied by contributors of the AGA 2018 President's Symposium: Origins of Adaptive Radiation. Yellow dots represent areas where field studies have been conducted and do not accurately represent the full geographic distribution of each group. different situations. Hence, treating it as a single phenomenon can preclude understanding of the interplay between factors including isolation, selection from the external environment, and interactions between close relatives within the radiation, in generating diversity within a given radiation, and how these differences may affect patterns of species accumulation through time.

Our goal in the current paper is not to defend a specific definition or concept but rather to embrace the diversity of viewpoints on the topic. Our overarching message is that progress in the field requires clear identification of the nature and timing of both speciation and ecological diversification. We begin our examination of adaptive radiation by outlining three elements that are necessary, though not fully sufficient to explain adaptive radiation—ecological opportunity, time, and adaptive response to ecological selection (Schluter 2000).

Attributes Common to Adaptive Radiation—Opportunity, Time, and Adaptive Response

Opportunity and Ecological Arena

Understanding adaptive radiation requires a joint focus on both ecological and evolutionary processes, and how each influences the other. Simpson (1953) proposed that the primary prerequisite for adaptive radiation to occur is ecological opportunity, which can arise in one of three ways: 1) colonization of underpopulated or underutilized areas; 2) a key innovation that allows a lineage to interact with the environment in a novel way; or 3) extinction of a previously dominant group. The radiations examined here are all extant and largely without good fossil records; we do not consider radiations that have

been largely eliminated through extinction (Morlon et al. 2011) nor do we address the importance of extinction in facilitating subsequent radiation (Feduccia 2003; Chen and Benton 2012; O'Leary et al. 2013; Hull 2015). As initially hypothesized (Simpson 1944, 1953), ecological opportunity arises in the form of ecological space that is unoccupied or underutilized by competing taxa, and that permits evolutionary diversification (Schluter 2000; Losos 2010). However, the opportunity provided by open ecological space is relative to the taxon in question and the response of a taxon to opportunity is necessarily dictated by niche discordance in concert with niche availability (Wellborn and Langerhans 2015).

A powerful form of ecological opportunity that affects many lineages is the colonization of novel habitats or areas that lack ecologically similar species largely due to barriers that limit colonization, such as geographic isolation. Situations providing ecological opportunity are perhaps most frequent on remote or newly formed islands and lakes, or upon adoption of a novel host or pollinator (Ehrlich and Raven 1964; Wheat et al. 2007). The ecological opportunity thus provided is an attribute of the community, rather than a given lineage although clearly the taxon must have attributes that allow it to take advantage of the ecological opportunity, such as ecological versatility (Stroud and Losos 2016). As such, ecological opportunity is related to the “taxon cycle” hypothesis (Wilson 1961; Ricklefs and Bermingham 2002a), in which early colonists to a site are successful and abundant, potentially due to “enemy release” and subsequently diversify into different specialized ecological niches. Thus, the response to ecological opportunity is linked to a shift in the balance between competitors, predators and prey, and/or parasites and hosts (Warren et al. 2015).

The importance of ecological opportunity points to the order of colonization as a key factor in dictating which lineages radiate and which do not. Priority effects from a diversifying lineage may prevent subsequent lineages from gaining a foothold or subsequently diversifying (Fukami et al. 2007; Fukami 2015; De Meester et al. 2016). Alternatively, a taxon in a nonradiating lineage may establish first, and remain limited to the ancestral niche; the presence of this lineage could preclude establishment by a secondary colonizer from the same lineage within that ancestral niche space, potentially facilitating ecological exploration in the secondary colonizer.

The amount of genetic variation will dictate the ability of a colonizing population in the new space to respond to selection and the rate of adaptive divergence from its mainland ancestor, whereas the degree of partial or complete geographic isolation combined with the dispersal capacity of taxa in the regional species pool will influence the rate at which the habitat can be filled with other colonizing species, reducing ecological opportunity for adaptive radiation. Subsequent diversification within the lineage will be shaped by the interplay of geographic separation, resources, competitors, predators, and parasites that will all change through time. Time is thus crucial in the “race” between adaptation and immigration (Emerson and Gillespie 2008; Gillespie and Baldwin 2010; Vanoverbeke et al. 2016). In the Hawaiian Islands, for example, the oldest of the current high islands (Kauai, ca. 5 million years old) emerged at a time when the previous islands were low and far apart (Price and Clague 2002). With the profound isolation from other high islands for ca. 1 Ma, there was greater time and opportunity for ecological exploration and diversification on Kauai (Gillespie 2016). Subsequent appearance of younger islands has been associated with increased opportunity for island hopping (Lerner et al. 2011) and hence less time for ecological exploration by a single lineage within an island. As a result, a number of lineages are characterized by ecological diversification on the oldest islands only, with colonization of the younger islands by island hopping of previously diverged ecological forms, as has been shown, for example, in flies (Magnacca and Price 2015), leafhoppers (Bennett and O’Grady 2013), and spiders (Garb and Gillespie 2009). Within any given radiation, the tendency for lineages to progress from older to younger islands (referred to as the ‘progression rule’) appears to be indicative of strong priority effects associated with original establishment on older islands inhibiting back colonization from younger islands (Shaw and Gillespie 2016).

Time and Rate

Adaptive radiation is frequently associated with an increase in the rate, or “early bursts” of species diversification as ecological opportunity is explored, followed by a slow down as niche space fills up, as has been shown in some classic adaptive radiations (Gavrilets and Losos 2009; Rabosky et al. 2013). However, adaptive shifts can occur without increased rates of diversification, as demonstrated in lineages of bromeliads in South America (Givnish 2015), assassin spiders (Wood et al. 2013), and vanga birds (Reddy et al. 2012) in Madagascar. And, finally, adaptive radiations are often associated with increased rates without any evidence for a slow down (Harmon et al. 2010); situations where diversification is adaptive without any increase in the rate of speciation could arise, for example, if the ancestral taxon has low levels of standing genetic or trait variation to allow adaptation to novel habitats. In this case, founding populations must rely on new mutations to catalyze each successive adaptive shift.

Adaptive Response

Radiations have been broadly characterized as adaptive or nonadaptive (e.g., Rundell and Price 2009), depending on the extent to which species have diversified ecologically. While classic adaptive radiation involves ecological shifts, nonadaptive radiations (clades that exhibit little ecological disparity) show ecological conservatism—at least in traits that can be easily measured—over evolutionary time scales. Initially defined as “evolutionary diversification from a single ancestor, not accompanied by relevant niche differentiation” (Gittenberger 1991), nonadaptive radiations are common in taxa with low dispersal ability, as in many (not all) snail and salamander lineages, that are hence easily isolated when their habitats become spatially subdivided (Wake 2006). Species formation in large radiations, however, can involve complex mixtures of niche divergence and niche conservatism (see below).

In summary, ecological opportunity, time, and adaptive response are necessary, although not fully sufficient, ingredients of all adaptive radiations surveyed here. The role that each of these factors plays, however, can vary considerably across radiations and even over time within a radiation. Clearly needed are analyses across multiple radiations that can examine how and when species diverge during the course of adaptive radiation. Given the variety of mechanisms through which adaptive radiation may be achieved, we compared a diversity of adaptive radiations studied by the authors to tap the experience and knowledge they have garnered of their respective research systems. Our hope is to discern common denominators and characterize differences in ways that can help guide further investigation.

Common Denominators Across Adaptive Radiations—Questions and Answers

After the conference, contributors were asked to address seven questions in relation to their study systems, with predefined alternatives from which to choose, and given freedom to speculate. The lineages under consideration, and on which the authors are experts, included: Hawaiian *Bidens* and *Metrosideros* plants; Galapagos *Naesiotus* land snails; Hawaiian *Tetragnatha*, *Ariamnes*, and *Mecaphesa* spiders; Hawaiian *Laupala* crickets; Hawaiian *Nesophrosyne* leafhoppers; Hawaiian *Drosophila* flies; Hawaiian *Hyposmocoma* moths; South American *Heliconius* butterflies; *Rhagoletis* fruit flies; North American threespine stickleback fish; East African cichlid fishes; pre-Alpine European whitefish; Mediterranean labrine wrasses; San Salvador Island pupfishes; Cameroon crater lake cichlid fish; Eastern plethodontid salamanders (*glutinosus* group); *Anolis* lizards of the Greater Antilles; mainland *Anolis* (subclade Draconura); Darwin’s finches; Tristan finches; and Hawaiian honeycreepers. These study systems are, of course, a partial and perhaps biased representation of all adaptive radiations. Nonetheless, they cover a diversity of taxonomic groups and geographic settings from which we seek to identify commonalities. The results suggest general principles that might be explored in other systems.

The answers (26–28 responses for each question) are given in [Supplemental Figure 1](#) and summarized below:

- I. How did your lineage gain access to the (novel/underutilized) eco-evolutionary space into which it radiated? The question here related to the role of ecological opportunity associated with geographic colonization of a new environment, or key innovations coupled with colonization of a new set of niches. For the radi-

ations examined, geographic colonization was the most common factor identified (78%), sometimes in conjunction with a key innovation (18%).

- II. How does the ancestral niche compare to what you know of the pattern of establishment of niches between species within the radiation? It is often difficult to determine whether the ancestor of a radiation was a generalist, or whether the generalist strategy arose during ecological release upon colonization of new ecological space. However, for the majority of lineages, including cichlids, *Anolis* lizards, Hawaiian insects, and *Metrosideros* plants, contributors speculated that the ancestral species was most often a generalist (43%), with subsequent diversification leading to multiple specialist species. In Hawaiian insects that feed on plants, colonizing ancestors may frequently have arisen from generalists that might have been polyphagous in their ancestral range, facilitating establishment in an ecosystem with restricted and depauperate flora (Bennett and O'Grady 2012). However, in other lineages (25%), it appears that the ancestor was likely specialized and underwent ecological release upon colonization of the islands, most notably for Hawaiian spiders, moths and crickets (Otte 1994), Galapagos snails, and possibly stickleback fish. In Hawaiian *Tetragnatha* spiders, for example, the sister lineage on the American mainland is widespread but restricted to riparian habitats, building flimsy webs over water, whereas the species radiation in Hawaii is found in almost every forest habitat and microhabitat (Gillespie 2016). Likewise, the most probable sister group to Galapagos *Naesiotus* snails is restricted to dry forest habitats, whereas Galapagos snails have adapted to a much wider range of habitats (C. Parent, unpubl) (Phillips et al. 2020). Similarly, phylogenetic reconstruction of extant Hawaiian honeycreepers suggests that the Cardueline colonizer was a finch-billed, seed-eating specialist; this morphology seems to have been lost at the onset of the honeycreeper radiation (Campana et al. 2020), with the finch morphology subsequently regained from a thin-billed ancestor (Lerner et al. 2011).

Whether ancestors were generalist or specialist, most radiations are associated with expansion of total niche breadth beyond that of the ancestral range, as has been shown in cichlids (Joyce et al. 2005) and in Hawaiian insects (Bennett and O'Grady 2012; Bennett and O'Grady 2013), likely due to both release from competition and/or release from predation and parasitism. A generalist ancestor can give rise to multiple descendant species that are not simply partitioning broad niche space, but are also (often greatly) expanding total niche breadth across the descendant species that exceeds that of the generalist common ancestor (e.g., Rubinoff and Schmitz 2010). In Hawaiian *Metrosideros*, population genetic analyses suggest the evolution of habitat specialists from a widespread more generalist taxon but with overall increase in niche breadth across the different species of the radiation (Stacy et al. 2014, 2020; Stacy and Sakishima in review). Members within a radiation are variably specialized, with some members no more specialized than the ancestor and some perhaps even less, with a classic example from Galapagos finches; that is, while the ancestral colonizer is not certain, the oldest species in the radiation are very specialized and some of the younger species in the radiation are broad generalists (Grant 1999; De León et al. 2014).

Tephritid fruit flies in the *Rhagoletis pomonella* sibling species group highlight an additional important consideration of standing ecological variation (or environmental plasticity) in regard to the question of specialist versus generalist. *Rhagoletis* flies attack the

fruit of different host plants and adaptively radiated via a series of sympatric host shifts from an ancestral hawthorn-infesting population (Bush 1969; Berlocher and Feder 2002). Thus, while the ancestor may be a specialist, a key trait involved in host shifting is the timing and synchronization of pupal diapause with host availability (Dambroski and Feder 2007). As a result, taxa are allochronically reproductively isolated. The ancestral hawthorn-infesting taxon, while a hawthorn specialist, shows latitudinal genetic variation in eclosion timing according to hawthorn fruiting schedules (Doellman et al. 2019), providing polymorphism to enable local shifts and ecological specialization on new hosts with varying fruiting times. Thus, diversification occurs in communities that are already rather full (Cornell 2013), as also may be the case in the *Heliconius* butterflies (Merrill et al. 2015).

III. In the initial establishment of the radiation, what is the pattern of niche occupation? This question addressed whether the radiation started by (1) initial establishment in a preferred niche and exclusion or nonappearance of subsequent colonists, followed by radiation into many other niches (Leigh et al. 2007), or alternatively, (2) exclusion from the ancestral niche (perhaps by earlier colonists which did not radiate) leading to initial establishment in novel niches and associated radiation. Many contributors (39%) considered that initial establishment occurred in the preferred niche with subsequent colonists excluded (cf. priority effects; e.g. in *Laupala* crickets Shaw and Gillespie 2016). Variations on these ideas were suggested for cichlids and Mediterranean labrine wrasses with initial establishment in the niche resembling the ancestral niche, although subsequent colonists were not excluded from that same niche even though they had substantial niche overlap (both in microhabitat and trophic resources) with the earlier colonists. Here, ensuing radiation has occurred by rapid "cladistic expansion" from this niche into many other niches. However, opinions varied widely even for the same lineage, likely reflecting the difficulties in obtaining data that would support one or the other scenario. Indeed, without a timeline, distinguishing between initial colonization in an ancestral niche with a subsequent shift versus direct colonization in a new niche without that first step into the ancestral niche, is challenging.

IV. In the course of adaptive radiation, what factors drive divergence between populations, some of which become species? There are two clear mechanisms through which initial reproductive isolation can occur. The first is ecological—divergent selection between different environmental conditions; the second is divergence in isolation without divergent ecological selection, though there may be sexually mediated divergent selection, and ecological divergence may arise subsequently due to biotic interactions.

Divergent or disruptive selection between different environmental conditions—This mechanism was suggested for all plants, fishes, Galapagos and Tristan finches, and *Rhagoletis* flies (46% responses). The numerous forms of *Metrosideros* apparently formed and persist by divergent selection with genetic incompatibilities contributing to partial reproductive isolation in hybrid zones (Stacy et al. 2017), with differential adaptation across successional (Morrison and Stacy 2014), elevational (Stacy et al. 2020), and riparian (Ekar et al. 2019) gradients. In Tristan finches (*Nesospiza* spp.), the original colonizers were small-billed (Stervander 2015); the arrival of a novel food source (fruits of the island tree *Phyllica arborea*) introduced disruptive selection pressure, which resulted in a miniature radiation into

replicate taxon pairs of small- and large-billed finches on each of two islands (Ryan et al. 2007; Stervander 2015). Similarly, selection for different environments, such as that associated with color pattern mimicry or host choice, appears to be the initial driver of divergence in *Heliconius* butterflies, and this drives changes leading to assortative mating based on color pattern and microhabitat (Merrill et al. 2015). Although genetic incompatibilities arise and are important even within some species, the strongest initial barriers between species appear to be predominantly ecological and sexual.

The distinction between divergent and disruptive selection is that the former occurs between populations and the latter occurs within them. Both contexts are found in adaptive radiations. In Lake Victoria cichlids, initial ecological selection between niches is often divergent rather than disruptive; however, disruptive selection emerges from the interaction of sexual selection with the environment (Seehausen et al. 2008; Moser et al. 2018; van Rijssel et al. 2018). Disruptive selection is evident in other cases of Lake Victoria cichlids, albeit few, such as in the genus *Neochromis* (van Rijssel et al. 2018), in Cameroon crater lake cichlids (Martin 2012), Tristán finches (Ryan et al. 2007), and Darwin's finches (Hendry et al. 2008). In some stickleback and Cameroon cichlids, disruptive selection gradients were only moderate in strength, suggesting that ecological selection was not sufficient to drive species divergence (e.g., Matessi et al. 2002; Bürger et al. 2006; Bolnick 2011). Alternatively, in one Cameroon cichlid radiation it appears that an influx of additional genetic variation for olfactory signals was the primary driver of speciation (Poelstra et al. 2018). In the pre-Alpine whitefish radiation (Hudson et al. 2011; Vonlanthen et al. 2012), divergent selection occurs between different spawning habitats (water depth), possibly coupled with disruptive selection on trophic adaptations in the feeding habitat (which is distinct from spawning habitat in these radiations).

Host shifts are linked to speciation events among native Hawaiian leafhoppers (Hemiptera: *Nesophrosyne*), though much of the ecological diversity among the >200 species in this lineage has resulted from ecological divergence between host-plants at the onset of the radiation (Bennett and O'Grady 2012) with subsequent diversification in allopatry without host shifts between islands (Bennett and O'Grady 2013). Symbiotic interactions with microbes may provide another—although currently poorly understood—evolutionary mechanism that may facilitate adaptive shifts and adaptive radiation more broadly (Poff et al. 2017). Symbionts are known to provide a number of beneficial traits to their hosts, permitting them to use resources and to persist in environments that may otherwise be unsuitable for hosts (Bennett and Moran 2015).

Divergence in isolation without (initial) ecological selection—A second mechanism through which initial divergence can occur is through intrinsic reproductive incompatibility that is ecologically independent (32% responses, or 46% in conjunction with divergent selection). Thus, anoles (Losos 2009; Stroud and Losos 2020), Hawaiian spiders (Cotoras et al. 2018; Gillespie 2005), and Galapagos snails (Phillips et al. 2020), all appear to demonstrate initial divergence in the same environment, though in allopatry presumably through intrinsic incompatibility. Ecological shifts are associated with subsequent secondary contact (Cotoras et al. 2018; Stroud and Losos 2020).

In a few situations (4% responses), contributors chose neither of the above responses for their lineage; rather, they suggested that divergence in isolation may be a slow process and lead to nonadaptive radiation. Thus, in the plethodontid salamanders of the eastern United States, populations became isolated following the formation of the

Appalachian mountain range (Kozak et al. 2006). Isolated populations were subsequently unable to maintain connectivity and diversified into ecologically similar and morphologically cryptic allo- or parapatric species that replace each other geographically (Kozak and Wiens 2010). Among spiders in the Hawaiian Islands, nonadaptive radiation has been well described in *Orsonwelles* (Linyphiidae) with 13 species across the islands: all species have similar ecologies, and species tend not to co-occur (Hormiga et al. 2003). Similar patterns of allo- and parapatric replacement of members within a lineage have been documented in many lineages including Galapagos mockingbirds (Arbogast et al. 2006), Galapagos tortoises (Beheregaray et al. 2004), Lake Malawi (Allender et al. 2003), and Lake Victoria cichlid fish (Seehausen et al. 1999), although there is often some difference between the environments occupied by the different taxa.

Sexual selection can also play a role in initial reproductive isolation without major ecological shifts and lead to very rapid diversification (4% responses). Thus, members of the native Hawaiian crickets in the genus *Laupala* share a similar niche but still display species coexistence with up to 4 species in sympatry. Although the specific mechanism of sexual selection is unknown, selection likely plays a role in speciation in this group producing sexually rather than ecologically differentiated groups (Otte 1994; Mendelson and Shaw 2005; Xu and Shaw 2019). However, since divergent sexual selection is often tied to ecology (e.g., Maan and Seehausen 2011), the distinction between adaptive and nonadaptive radiation can become blurred.

V. In the course of adaptive radiation, do species have long-term persistence or are they ephemeral? This question asks whether most entities persist, once formed; or whether they are ephemeral, eliminated by ecological or evolutionary processes of exclusion, introgression upon secondary contact, reversal of speciation, or demographic stochasticity (Rosenblum et al. 2012; Seehausen et al. 2008). These ideas build on those of ephemeral diversification, wherein most diverging groups never diverge to the point of being permanently isolated species (Futuyma 1987). The opinions of contributors were divided between those that considered the focal lineages were ephemeral (39%) versus persistent (39%). The fate of ephemeral forms varied among lineages. In sticklebacks, it appears likely that many freshwater forms are ephemeral and have been extirpated by multiple mechanisms, including demographic stochasticity in addition to environmental processes and introgression. For instance, ice ages likely obliterated most freshwater forms of stickleback, such that many of today's forms have evolved from marine forms only since the most recent glaciation. Likewise in pupfishes, reproductively isolated ecotypes may routinely go extinct due to environmental or geological processes such as loss of hypersaline lake environments. For radiations involving slow-to-speciate taxa such as Hawaiian *Metrosideros* trees, the presence of multiple morphologically distinct yet weakly genetically diverged forms may result from the lack of persistent divergent selection on unstable volcanic islands (Stacy et al. 2020) and species boundaries will likely disappear through introgression in this highly interfertile group. Likewise in Hawaiian *Bidens*, species are generally fully isolated either by geography (on different islands) and/or by habitat (and pollination syndrome for the one bird pollinated *B. cosmoides* on Kauai), but when secondary contact occurs the species can meld back together into hybrid swarms since intrinsic reproductive isolation has not yet occurred amongst any of the endemic Hawaiian species tested

(Ganders and Nagata 1984; Knope et al. 2013; Knope et al. 2020). However, all Hawaiian species tested are intrinsically isolated, likely by genetic incompatibilities, from taxa in their hypothesized Central American sister clade (Knope et al. 2013), and this reproductive incompatibility appears to have arisen within the past ~2 My (Knope et al. 2012, 2020).

Genetic evidence suggests widespread mtDNA leakage in Hawaiian *Laupala* crickets, suggesting persistent hybridization across the radiation (Shaw 2002; Shaw and Gillespie 2016); nonetheless, two clades of this group have maintained genetic distinctiveness in sympatry for at least 3.5 My (Mendelson and Shaw 2005). In *Heliconius* butterflies, where local sympatry of sister species is widespread, gene flow plays a role in persistence of species (Rosser et al. 2015); here, species differentiation is maintained by the occupation of different niches and assortative mating, potentially aided by F1 female hybrid sterility and pleiotropic effects of mimicry, habitat and host plant shift leading to assortative mating (Merrill et al. 2015).

In Lake Victoria cichlids, timelines are very short, yet >500 species have evolved in a time frame similar to that of sticklebacks, the latter having evolved at most two species in sympatry. Thus, most cichlid taxa are predicted to persist at least for thousands of years (which is long in a 15,000-years-young radiation), but some are likely to have been eliminated by speciation reversal. The scale of speciation reversal is mediated by environmental change (natural and anthropogenic), and the impact can be massive in parts of the radiation.

VI. In the course of adaptive radiation, which factors best describe achievement of species co-occurrence? Contributors working on Caribbean *Anolis* (Losos 2009; Stroud and Losos 2020), Hawaiian spiders (Cotoras et al. 2018), Hawaiian *Drosophila* fruitflies, Hawaiian *Nesophrosyne* leafhoppers, and Darwin's finches (43% responses) argued that new incipient species often share ecological requirements when they come into secondary contact. Here, character displacement—potentially arising from plasticity in ecological traits (Pfennig and Pfennig 2012b)—gives rise to ecological divergence in sympatry (Brown and Wilson 1956). Likewise, among South American mainland radiations of *Heliconius* butterflies, ecological character displacement may begin very early during divergence to become the major driving force of speciation with gene flow (Rosser et al. 2015). However, in the Hawaiian *Laupala* crickets, species are largely similar in ecology, with the most closely related species largely allo- or parapatric; divergence in mate recognition apparently stabilizes taxa in sympatry without ecological displacement (Xu and Shaw 2020).

In other groups (21% responses), some form of ecological divergence appears to be involved prior to sympatry of taxa. In sympatric stickleback species pairs (see above), ecological character displacement is facilitated by initial divergence between environments. In Lake Victoria cichlids likewise, co-occurrence appears to often come about perhaps via having somewhat distinct ecologies that evolved during parapatric speciation before coming back into full sympatry (Figure 2, Seehausen 2015); however, character displacement likely also plays a role (van Rijssel et al. 2018). In Hawaiian *Metrosideros* trees, ecological divergence with gene flow may best explain the origin of morphotypes, given its exceptional dispersibility (Dawson and Stemmermann 1990). Similarly, in *Rhagoletis* flies, where there is no evidence for character displacement, ecological divergence with gene flow via host shifting is initially responsible for the divergence and co-occurrence of taxa (Bush 1969; Berlocher and Feder 2002).

VII. What are the underlying genetic and demographic conditions that lead to ecological disparity? The first part of this question (Supplementary Figure S1, VIIa) addressed the relative importance of admixture, developmental plasticity, evolvability (standing variation and the potential for new mutation), and/or lineage priority in paving the way for ecological disparity. Clearly, all of these processes may play a role and it is their interaction that may promote adaptive diversification; essentially all of the contributors at the conference answered the question in this manner. In several groups (25%), hybridization likely contributes to diversification. Stickleback evolvability is enhanced by standing genetic variation in the ancestral form (marine), but an important source of this variation is likely admixture between marine and older freshwater populations (Colosimo et al. 2005; Roesti et al. 2014). Admixture may also contribute to genetic variation in other fishes. For example, in many cichlid groups, including those from the African Great Lakes and Cameroon crater lakes, hybrid swarms may facilitate the onset of adaptive radiation (Stelkens et al. 2009; Meier et al. 2017; Irisarri et al. 2018; Poelstra et al. 2018) (see below). In San Salvador Island (Bahamas) pupfishes, adaptive introgression from a distant island 10 ka contributed to the divergent trophic morphology of specialists in the radiation, perhaps arising from a previous ephemeral radiation (Richards and Martin 2017). In *Heliconius*, introgression among lineages may lead to hybrid speciation (*Heliconius* Genome Consortium 2012) and, possibly, to more radiation (Merrill et al. 2015). Similarly, for the ancestral hawthorn-infesting population of *Rhagoletis pomonella*, part of the standing variation in diapause life history timing contributing to sympatric host shifts and speciation has an earlier history related to previous allopatric isolation, divergence, secondary contact, and admixture, beginning ~1.5 Ma that created latitudinal inversion clines (Feder et al. 2003). Admixture likely also contributed to evolvability in Galapagos finches (Lamichhaney et al. 2015; Chaves et al. 2016). However, other groups, including Hawaiian spiders (Cotoras et al. 2018) and honeycreepers (R. Fleischer, unpublished; Lerner et al. 2011; Knowlton et al. 2014) show little evidence of hybridization playing an ameliorative or other role.

The second part of this question (Supplementary Figure S1, VIIb) examined the extent to which disparity evolves repeatedly for lineages that occur in discrete areas (e.g., islands within an archipelago or a network of habitats across the landscape). Of the 26 responses, 15% considered that ecological disparity arose almost exclusively at the outset of the archipelago-wide radiation (species related across islands show niche conservatism). This was notable in Hawaiian *Hyposmocoma* moths (Haines et al. 2014), Hawaiian crab spiders (Garb and Gillespie 2009), Hawaiian *Nesophrosyne* leafhoppers (Bennett and O'Grady 2013), and Hawaiian honeycreepers (Lerner et al. 2011). In other lineages (58%), ecological disparity appears to have arisen repeatedly during the radiation. Here, diversification may occur in a replicated fashion (same ecological sets of taxa on each island/lake). This pattern is well known in the ecomorphs of Caribbean *Anolis* (Losos 2009), Tristan finches (Ryan et al. 2007), cichlids of the African Great Lakes (Muschick et al. 2012; Brawand et al. 2014), Hawaiian *Tetragnatha* spiders (Gillespie 2004), and Hawaiian *Ariamnes* spiders (Gillespie et al. 2018). Repeated evolution is also found among the ecotypes and ecomorphs of sticklebacks (Schluter and McPhail 1992; Rundle et al. 2000; Paccard et al. 2020) and the ecomorphs of Alpine whitefish (Vonlanthen et al. 2012). In

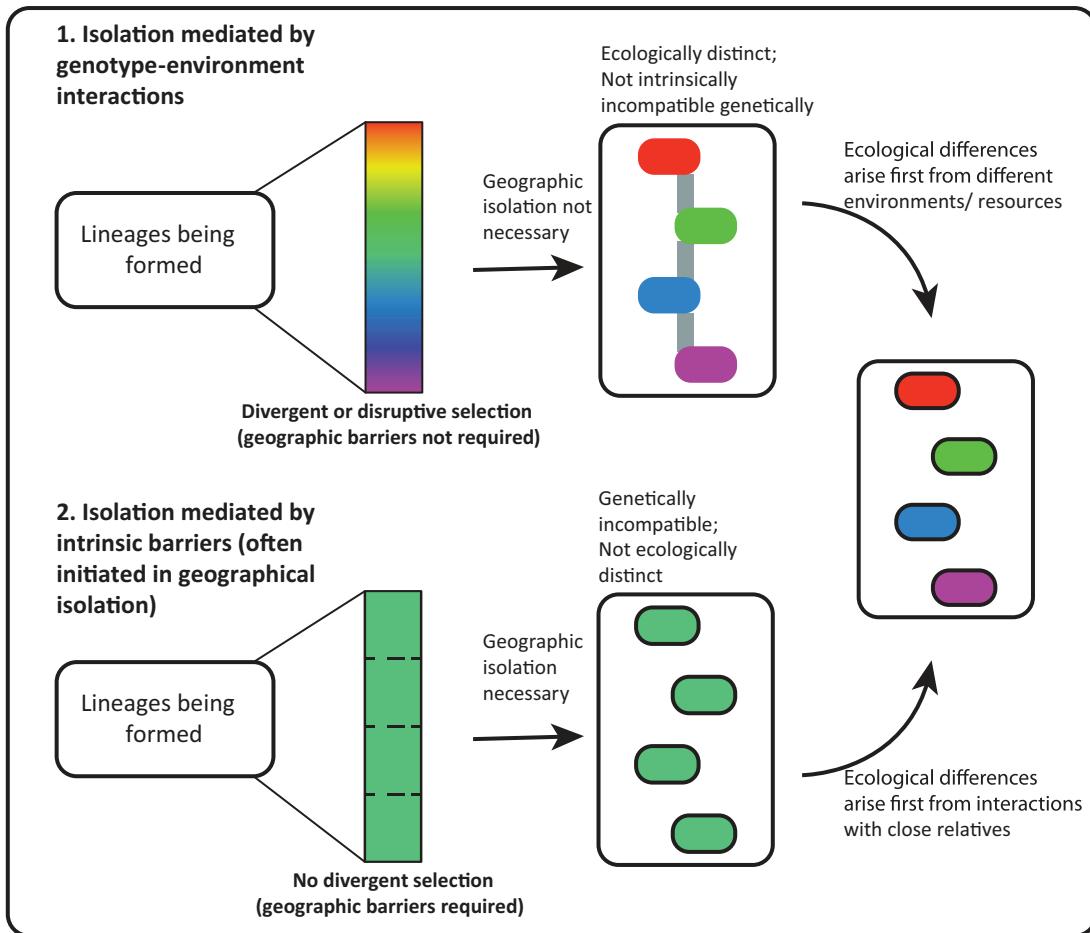

Figure 2. Contrasting roles of: (1) factors external to the membership of the radiation coupled with divergent or disruptive selection associated with the environmental conditions or resource or host use; versus (2) reproductive incompatibility within the same environment fostering initial divergence, with ecological divergence, if it occurs, happening later and associated with interactions between relatives internal to the radiation. Part (1) is detailed further in Figure 3; part (2) in Figure 4.

still other lineages, the pattern of diversification between islands is unpredictable, notably in Cameroon crater-lake cichlids, Caribbean pupfishes, Galapagos land snails, and Hawaiian *Metrosideros*. Other responses included variations or combinations of these effects. In stickleback, for instance, predictability of divergence is highly dependent on spatial scale, being much higher on regional than global scales (Paccard et al. 2020).

On the basis of the responses above, we discuss generalities of how and when species diverge *within* a lineage that is undergoing adaptive radiation, in the context of (1) initial divergence, (2) persistence of reproductive isolation and achievement of local sympatry, and (3) admixture leading to exchange of adaptive traits among diversifying lineages.

Common Denominators—How Do Populations Within a Radiation Gain Reproductive Isolation

To initiate species formation in the course of adaptive radiation, generally a population must establish in new environmental conditions or in a new geographic location with the same environmental conditions (Mayr 1947; Coyne and Orr 2004), although there are exceptions (Hendry et al. 2009; Mallet et al. 2009; Feder et al. 2012; Hendry 2016). Reproductive isolation may develop quickly

(Wheat et al. 2006), in particular when taxa that established some incompatibilities in allopatry, come together in sympatry (Coyne and Orr 1997); likewise, divergence may occur rapidly through ecological (Stuart et al. 2014; Dufour et al. 2017) or reproductive (Pfennig and Pfennig 2012a) character displacement. Given that speciation in sexually reproducing organisms involves the evolution of barriers to gene flow between populations, it is more likely to proceed when spatial, temporal or environmental separation restricts migration (Coyne and Orr 2004). Thus, it is important to consider how geographic barriers on the one hand and ecological shifts on the other hand facilitate species formation, including the time scale and relative order in which these arise, and their subsequent effect on the gene flow within and between populations.

Initial separation of populations in an adaptive radiation may be achieved in different ways, and comparisons across radiations often fail to find commonalities. While the first step clearly requires the origin of a new population, and stable co-occurrence of sibling species requires a mechanism to overcome gene flow (Seehausen et al. 2014), initial divergence may or may not involve different ecological selection pressures (Mayr 1947; Fig. 2). Factors that drive initial divergence can be broken down into two broad categories relative to the radiation: external and internal. We define external factors as those that involve interactions with the environment external

to the radiation membership (e.g., the physical environment or other unrelated species); external environmental effects tend to be coupled *with* divergent or disruptive selection (Figure 2.1). In other situations, genetic incompatibilities can arise without the need for interactions with the external environment and *without* external divergent selection (Figure 2.2), potentially linked to secondary sexual traits (Mendelson et al. 2014); subsequent ecological divergence (if it occurs) is likely associated with interaction among close relatives within the radiation (internal) (Brown and Wilson 1956; Pfennig and Pfennig 2010; Tilman and Snell-Rood 2014). The importance of these two mechanisms is also related to the rate of speciation and the degree and duration of geographic isolation, which we discuss later. Divergent sexual selection, depending on the specific mechanism and the role of the environment, may fit comfortably within either category.

Reproductive isolation coupled with divergent selection from the external environment

When initial reproductive isolation and ecological shifts are shaped by adaptation to the environment, speciation may proceed as a consequence of divergent selection in either the presence or absence of gene flow (Schluter 2001, 2009; Rundle and Nosil 2005; Nosil 2012) (Figure 2.1). For example, Galapagos wolf spiders (De Busschere et al. 2010) and beetles (Hendrickx et al. 2015) have repeatedly adapted to high and low elevation habitats. Similarly, host switching in parasites (Bush 1969; Price 1980; Feder et al. 1988; Drès and Mallet 2002; Forbes et al. 2009; Hood et al. 2015) or different pollinator communities (Schemske and Bradshaw 1999; Whittall and Hedges 2007) can generate new taxa via divergent ecological selection. This mechanism of initial divergence has been implicated in many other situations where populations respond to divergent selection in different environments, and can be accentuated by intra-specific competition within populations (Bolnick 2004; Levis et al. 2017). The very young lineages of sticklebacks and pupfish show strong evidence of divergent selection in the early phases of divergence (Schluter 2000; Hendry et al. 2009; Martin and Wainwright 2013), as do *Rhagoletis*, and other phytophagous insect specialists (Berlocher and Feder 2002). In each of these examples, the external environment leads to some kind of assortative mating (Richards et al. 2019); hence, species formation is explicitly tied to ecological differentiation.

Reproductive isolation coupled with geographic isolation

Isolated populations experiencing similar selective environments can evolve intrinsic genetic incompatibilities that arise by chance (Figure 2.2). When reproductive barriers are made up of intrinsic genetic incompatibilities, the taxa formed may be less prone to collapse or extinction than those arising from divergent selection alone (Seehausen 2006). Relative to extrinsic postzygotic or prezygotic incompatibilities that evolve under divergent selection (Seehausen et al. 2014), intrinsic incompatibilities that evolve by chance between populations may accrue at a slower rate (Price 2010). However, the rate at which intrinsic incompatibilities accumulate can be accelerated by parallel (non-divergent) selection as in speciation by “mutation-order” (Mani and Clarke 1990), where reproductive isolation evolves as a by-product of the fixation of different advantageous mutations between geographically isolated populations experiencing similar selection pressures (Schluter 2009). Moreover, population genetic models indicate that reproductive incompatibilities between populations initially experiencing similar

natural and sexual selection can be amplified as a result of sexual traits (Agrawal et al. 2011; Mendelson et al. 2014): Secondary, sexual traits can fix differently in different populations that initially experience similar natural and sexual selection, with sexual preferences persisting even with low levels of gene flow (Mendelson et al. 2014). Such effects can lead to the rapid origins of ecologically similar taxa in allo- or parapatry (Rundell and Price 2009). Thus, species formation here is not explicitly tied to ecological differentiation. However, when sibling species come into contact, reproductive isolation may be accentuated rapidly due to reinforcement (Coyne and Orr 1997). Moreover, ecological differences can then arise through character displacement (Weber et al. 2017; Cotoras et al. 2018).

Which taxa are likely to diverge in which way?

In studies of reproductive isolation within an adaptive radiation, it can be difficult to distinguish the relative importance of reproductive isolation coupled with divergent selection from the external environment (Figure 2.1) versus reproductive isolation coupled with geographic isolation and without divergent selection where ecological differences may evolve later through character displacement (Figure 2.2). We often lack an adequate temporal framework over which to compare early stages with later stages of a radiation. Thus, in many of the classic examples of divergence of sympatric species pairs (e.g., stickleback (Schluter and McPhail 1992; Rundle et al. 2000; Boughman 2001) and *Timema* walking stick ecotypes (Nosil 2007)), the lineages are very young and diversity is low (single species pair). While these cases have allowed measuring selection at early stages of species divergence, in many of these cases it remains unknown whether one speciation event will lead to adaptive radiation of multiple co-occurring species (Glor 2010; Losos 2010; Stroud and Losos 2020), and what role ecological interactions among species within the radiation might eventually play in promoting or constraining further species and phenotypic diversification (Martin and Richards 2019).

As might be expected due to their often fine-tuned response of plants to local environmental conditions (Anacker and Strauss 2014), most plant radiations highlight the role of environmental factors external to the radiation and divergent ecological selection in the early stages of speciation; for example, despite exhibiting greater morphological and ecological diversity than the rest of the ~230 species in the genus distributed across five continents, divergence in Hawaiian *Bidens* appears to be driven by external factors in that all endemic species tested are cross-compatible, yet 70% of the 19 Hawaiian species are single-island endemics, and 85% are allopatric (or parapatric) when additionally considering habitat isolation within islands. Similarly, the numerous, predominantly intraspecific and co-occurring morphotypes of Hawaiian *Metrosideros* also show local adaptation to contrasting environments (e.g., Ekar et al. in review; Morrison and Stacy 2014), Sakishima et al., in prep.). Other plant radiations show a similar pattern of divergence between different environments, including silverswords and *Schiedea* in Hawaii, and various angiosperm clades in the Canary Islands (Gillespie and Baldwin 2010).

In contrast to divergent ecological or disruptive selection between environments (Maynard Smith 1966; Schluter 2009), resources, or hosts (Agrawal et al. 2011), there are multiple lineages in which initial reproductive isolation is coupled with geographic isolation and without divergent selection. The importance of isolation without divergent selection may be more pervasive in animals than plants (Anacker and Strauss 2014). The lack of divergent selection may lead

to a necessity for more time needed for development of reproductive isolation (Price 2010). However, intrinsic reproductive barriers can develop more quickly when coupled with effects such as mutation order mediated by sexual selection (Mendelson et al. 2014). The role of geographic isolation without apparent divergent selection between ranges, has been demonstrated in Hawaiian spiders (Gillespie 2005; Cotoras et al. 2018), crickets, and flies (Hiller et al. 2019), as well as in planthoppers (Goodman et al. 2012). It has also been suggested for the early stages of divergence in *Anolis* lizards (Glor et al. 2003, 2004; Knouft et al. 2006; Stroud and Losos 2020) where diversification occurs within the same climatic niche (Wogan and Wang 2019), as well as in Galapagos snails (C. Parent, unpubl. data).

To conclude, the mechanism through which initial divergence is achieved during the course of an adaptive radiation varies considerably across radiations, depending on the role of divergent or disruptive selection in the initial divergence of populations (Mendelson et al. 2014). In many situations, especially in plants and taxa with tight associations to a resource, populations can diverge in response to selection that is divergent or disruptive and external to the radiation (Schlüter 2001) (Figure 3). Alternatively, populations can diverge through adaptation to the same environment; in this case, ecological divergence—if it occurs—arises subsequently through interaction between relatives within the radiation (internal) (Rundell and Price 2009; Cotoras et al. 2018; Hiller et al. 2019) (Figure 4).

Common Denominators—Persistence and Sympatry Within the Radiation

Genetic entities, whether distinct populations or incipient species, are formed continuously during adaptive radiation but most are likely to be ephemeral (Rosenblum et al. 2012). This is a general expectation from neutral theory, and not limited to adaptive radiations, as most species are expected to emanate from small local populations, which are then prone to extinction (Leigh 2007). Nevertheless, speciation rates estimated from the fossil record are much slower than those predicted both from mathematical models and empirical data from recent radiations (Seehausen et al. 2014). Thus, while speciation—or at least the formation of phenotypically distinct ecotypes—may be common and rapid in the context of adaptive radiation, most new entities may be short lived. Evolutionary studies should therefore focus on not only the formation of new species but also their *persistence* in space and time.

In the case of lineages that are in the very beginning stages of a radiation, many reproductively isolated ecotypes may form, but they tend to be eliminated by geological or climatological processes such as loss of lake environments (e.g., paleo-lake Makgadikgadi: (Joyce et al. 2005)), or by glaciation (e.g., stickleback and whitefish), or by ecological processes of predation and exclusion (e.g., stickleback (Gow et al. 2006; Taylor et al. 2006), Lake Victoria cichlids (Goldschmidt 1998; McGee et al. 2015) and Laguna Chichancanab pupfishes (Strecker 2006)). Another cause of nonpersistence of many species in adaptive radiations is that as long as reproductive isolation (and hence speciation) is only a consequence of divergent adaptation to alternative fitness optima or ecological niches, species will persist only as long as the fitness optima exist. Fitness landscapes can change with changes in the physical and biotic environment, and when such changes lead to the convergence of formerly distinct fitness peaks, the mechanism of reproductive isolation will no longer persist, and species will coalesce back into a single gene pool (although see discussion of the issue of population persistence above).

Such speciation reversal has been described in adaptive radiations of cichlids (Seehausen et al. 1997), stickleback (Taylor et al. 2006), whitefish (Vonlanthen et al. 2012), and Darwin's finches (Hendry et al. 2006; Kleindorfer et al. 2014), and it may be widespread in highly sympatric radiations in general.

A major question centers on the circumstances that lead to the persistence of entities as adaptive radiation proceeds and as the environmental theater changes. To get at this, we must first assess the hallmarks of adaptive radiation, notably the context of co-occurrence that allows species to accumulate, and at what scale (i.e., between sites or within sites). The geography of co-occurrence varies considerably among adaptive radiations: members of a radiation can occur in allopatry, parapatry, mosaic allopatry, or pure sympathy, including syntopy. By definition, allopatry, parapatry, and mosaic allopatry all imply some level of spatial (or temporal) separation of populations, while sympathy connotes extensive dispersal between populations (Mallet et al. 2009) or that individuals are physically capable of regular interaction (Mendelson and Shaw 2005; Weber et al. 2017). For the purpose of understanding adaptive radiation, a critical component is determining whether and how individuals of diverging populations interact when they are in proximity.

Entities shaped by the external environment and divergent selection

Divergent ecological selection can lead to reproductive isolation between descendant lineages, owing to genotype by environment interactions that disfavor intermediate ecological phenotypes (Figure 3). Such divergence may occur at various scales of geographic separation. For example, taxa may diverge across broad elevation zones (De Busschere et al. 2010) leading to sympatry at the island level but with limited interactions between ecotypes. Similarly, many sister species in adaptive radiations of fish in lakes and in the Sea diverge along water depth gradients, as has been shown for cichlid radiations, Alpine lake whitefish and Pacific Ocean rockfish (Seehausen and Wagner 2014). Some plants may differentiate based on fine-scale environmental heterogeneity (Anacker and Strauss 2014). In some fish, the tendency to specialize either on a littoral/benthic or a pelagic/limnetic life history gives rise to divergent selective pressures between juxtaposed habitat types. When sufficiently strong, or sufficiently strongly coupled to habitat structure, such divergent selection may sometimes lead to speciation without geographical isolation (Barluenga et al. 2006; Richards et al. 2019). However, in all of these situations, it is the external environment that plays the major role in shaping ecological and mating traits of the organism.

Maintenance of nascent species and secondary sympathy

For nascent species adapted to different environments, their maintenance as genetically distinct entities often, but not always, requires ongoing divergent selection, at least until genetically intrinsic reproductive incompatibilities accumulate (Calabrese and Pfennig 2020) (Figure 3.2). These nascent species will be vulnerable to ecological perturbations that disrupt the regimes of divergent selection and dispersal (Nosal et al. 2009). Thus, lineages formed through ecological speciation as a result of divergent selection between different external environments in parapatry, may be vulnerable to loss due to changes in selective regimes (Cutter and Gray 2016). The same would apply to cases of allopatric ecological speciation when changes in the selective regime coincide with a loss of a geographical barrier or change in dispersal regime. The temporal scales over which environments change and intrinsic incompatibilities become fixed within

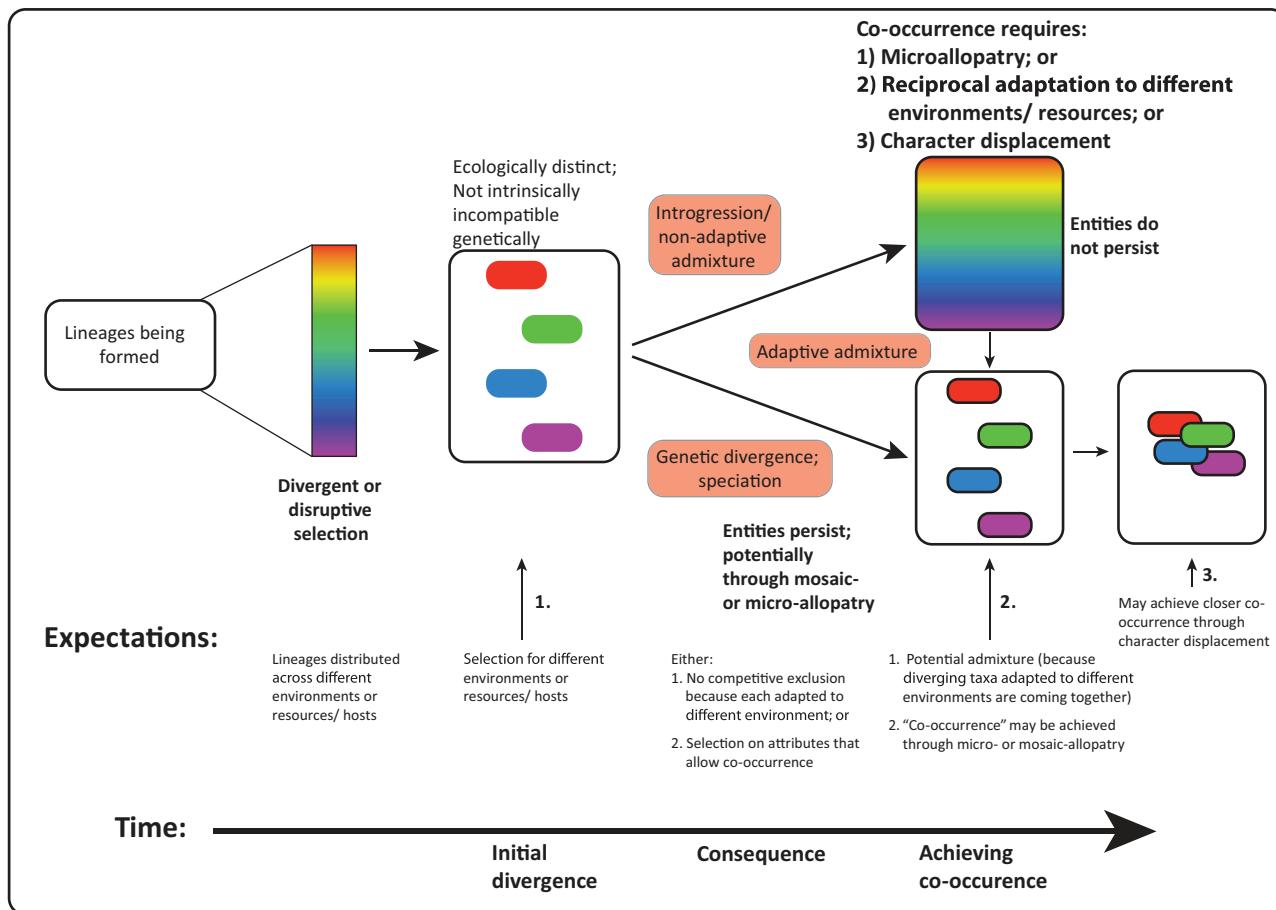

Figure 3. Entities formed by factors external to the radiation membership and associated with divergent or disruptive selection (building on Figure 2, part 1). The external environmental conditions and divergent or disruptive selection can lead to reproductive isolation between descendant lineages, owing to genotype by environment interactions. In some lineages, tighter co-occurrence can be achieved through character displacement in secondary contact.

diverging populations are therefore important issues when reproductive isolation is initially based on such divergent selection.

Maintaining divergent selection

Based on the arguments above, it is likely that entities formed in the context of divergent selection between different external environments will tend to persist as long as the pressure imposed by divergent selection is maintained (Seehausen et al. 2014). When these divergent selection pressures are due to differences in host, pollinator, or habitat fidelity where organisms preferentially choose to reside and mate in their natal habitats, positive assortative mating can emerge as a consequence of the interplay between habitat choice, mate choice, and performance. As a result, gene flow between habitats is reduced and population divergence accentuated in a process analogous to reinforcement except that further differentiation of habitat preference occurs rather than preference of mates (Thibert-Plante and Gavrilets 2013). One example of this occurs in *Rhagoletis* flies that mate only on or near the fruit of their respective host plants and that use volatile compounds emitted from the surface of ripening fruit as key olfactory cues to discriminate among alternate hosts and mating arenas (Linn et al. 2003; Powell et al. 2012). If the divergent selection is strictly between spatially distinct environments, local (alpha) diversity of species cannot increase, but beta diversity may increase by increasing the spatial turnover as a result of increasingly tight associations with a given microenvironment, with mosaic or micro-allopatry (Figure

3.2). When the divergent selection is between microallopatric niches (such as host plants in *Rhagoletis*), the emerging species can be effectively sympatric at least for parts of their life cycle.

Order of events

The "habitat first rule" of adaptive radiation suggests that initial divergence often occurs as a consequence of environmental variability across space (Schlüter 2000). A similar scenario has been suggested in a general vertebrate model (Streelman and Danley 2003).

Entities Shaped by Intrinsic Reproductive Isolation and Ecological Divergence in Secondary Sympathy

The alternative to separation along the environmental/habitat boundary is separation in geographical space without any obvious divergent selection (Figure 4). In this case, populations, usually in similar environments, become isolated for a period of time (Figure 4.1), potentially sufficient to lead to the fixation of genetic incompatibilities as a result of genetic drift or parallel selection interacting with mutation order (Mendelson et al. 2014). Here again, after such isolation, taxa may or may not come back into contact.

Secondarily gaining local sympatry

First, interaction in local sympatry may be readily achieved for entities thus formed because the environments in which sister taxa

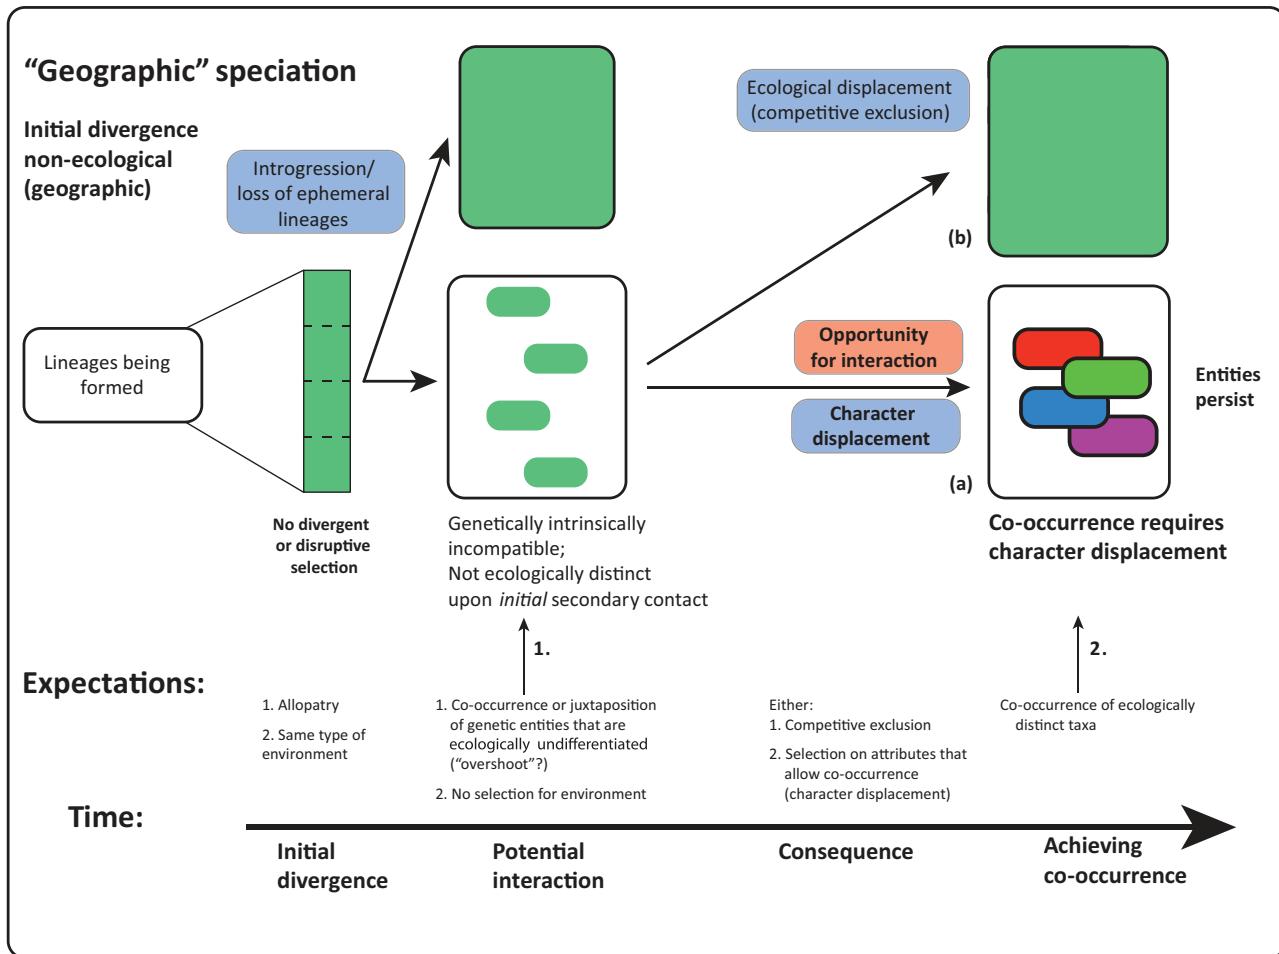

Figure 4. Entities formed by reproductive incompatibility within the same environment—separation in geographical space without any obvious divergent or disruptive selection (building on Figure 2, part 2). Ecological divergence may arise through interaction with close relatives within the radiation subsequent to the development of reproductive incompatibilities.

have diverged are similar (Cotoras et al. 2018). Moreover, at least in some taxa, behavioral (prezygotic) reproductive isolation can be achieved upon secondary sympatry when sister taxa are already isolated by postzygotic incompatibilities; these events can precede the evolution of ecological or morphological differences (Orr 1995). Then, the expectation is that when ecologically similar but reproductively isolated taxa come together, competition for shared limiting resources will lead to ecological character displacement (Figure 4.2a) which stabilizes the coexistence of competing species in sympatry (Germain et al. 2018). Alternatively, competitive exclusion may lead to geographical disjunctions or extinction of one of the taxa (Figure 4.2b) (see section below). Of course, niche overlap can vary in space and time and, hence, species with broad niche overlap during much of the year can still coexist as long as they show substantial niche separation during critical periods (De León et al. 2014). Which of these outcomes occurs, when, and why some lineages are more prone to one or the other outcome of competition, is an open question.

Remaining in allopatry

Second, sibling taxa may remain in allopatry as in the classic form of nonadaptive radiation (Rundell and Price 2009) (i.e., remaining as shown in Figure 4.1) or they may persist in various forms of parapatry, microallopatry, or mosaic allopatry, but again without much local interaction.

Order of events

Unlike the “habitat first” model discussed above, when reproductive isolation occurs without any notable ecological shift, the first ecologically divergent traits to appear will be those associated with interactions arising from secondary sympatry of sibling species. This has been noted in a radiation of western North American *Ceanothus* (Ackerly et al. 2006), with traits that allow co-occurrence being the first axis of ecological divergence after complete allopatric speciation.

The arguments presented here come with many caveats because phylogenies cannot be used to reliably infer the geography of speciation (Losos and Glor 2003) and phylogenetic reconstructions are simply hypotheses, with inherent uncertainty. Without witnessing a temporal sequence of events, it is very difficult to test alternative hypotheses or to infer the role of extinction on these clade-level patterns. Some hotspot island archipelagoes or lakes that span a spectrum of ages have been used as temporal snapshots to reconstruct the evolutionary history of lineages (Shaw and Gillespie 2016), though here again, there are assumptions that taxa do not violate the temporal sequence (e.g., through “back colonization”).

To conclude, during adaptive radiation, when differentiation is tied to the external environment or habitat types (e.g., host or other associate), divergent selection between environments or hosts may often play the dominant role in shaping patterns of diversity (Figure 3).

Persistence of nascent species, thus, generally requires ongoing divergent selection for alternate environments or associates. In a number of lineages, however, ecological divergence is achieved subsequent to geographic isolation, through direct interaction between close relatives internal to the radiation, leading to accumulation of local diversity through ecological character displacement (Figure 4).

Common Denominators—Isolation and Admixture

Early work on speciation stressed the importance of geographic isolation between populations, with mutation, genetic drift and indirect effects of natural selection causing speciation. It was generally believed that gene flow would counteract differentiation between populations, and research focused on isolating mechanisms that prevented gene flow (Merrell 1962). The rapidity of adaptive radiation in some systems then suggested various ways that differentiation could be achieved, with much attention focused on founder events and the possibility that premating isolating mechanisms could evolve quickly through sexual selection. Subsequent studies on *Drosophila* showed that both prezygotic and postzygotic reproductive isolation increase with divergence time between taxa, but secondary sympatry, or syntopy after extensive periods of allopatric divergence, has a very strong effect on increasing the rate at which prezygotic isolation can evolve, likely through selection for sexual recognition among genetically compatible genotypes (Coyne and Orr 1997). Various mechanisms have been proposed to explain elevated rates of divergence, including chromosomal rearrangements that can prevent recombination and allow genomic regions to diverge in the face of gene flow (Machado et al. 2007). While the importance of geographic isolation is widely accepted (Coyne and Orr 2004), occasional gene exchange may continue long after speciation, and quite often for species that are millions of years divergent (Grant and Grant 1992; Arnold 1997; Mallet 2005, 2008). Thus, speciation can occur without complete geographic isolation (Mallet 2008; Servedio and Noor 2003), in particular given sufficient divergent or disruptive selection and its association with mating habitat (Bush and Butlin 2004).

Given the above, it may initially come as a surprise that hybridization leading to genetic admixture may even facilitate adaptive radiation. Two distinct scenarios have been proposed (Seehausen 2004): 1) admixture occurring among nonsister species within/during an adaptive radiation may facilitate further speciation within the adaptive radiation, a concept known as the *syngameon hypothesis* (Seehausen 2004; Givnish 2010); and 2) admixture between distantly related species prior to adaptive radiation may facilitate the onset of adaptive radiation from the hybrid population, a concept referred to as *hybrid swarm origins* (Figure 5, Seehausen 2004). For ongoing speciation, gene flow between diverging populations will often stall further divergence. However, gene flow into one of two diverging populations from a third, more distantly related, population or species can allow the recruitment of alleles that may facilitate the divergence between the sister populations (Poelstra et al. 2018). Recent studies have started to focus on the genomic signatures and evolutionary consequences of admixture. When previously divergent populations come together, hybridization may lead to introgression which is genetically quantified as “admixture”. Its extent and genomic distribution depends on the degree and nature of genetic divergence between the entities involved prior to their contact, given the tendency for genetic incompatibilities to increase with time and genetic divergence (Matute et al. 2010). However, the frequency of

phenotypic novelties that can arise spontaneously as a consequence of hybridization also tends to increase with time for divergence (Stelkens et al. 2009). Recent experimental work shows how both the genetic difference between hybridizing species and the number of species that contribute to a hybrid population affect the probability of reproductive isolation in the hybrid population. There appears to be a “sweet spot” between the minimum divergence necessary for the evolution of novel and advantageous recombinant genotypes and a maximum divergence, beyond which the accumulation of genetic incompatibilities eliminates any evolutionary impact of hybridization (Comeault and Matute 2018). These sweet spots of divergence prior to hybridization have the potential to play a key role in adaptive radiation, although the minimum and maximum divergence may differ greatly for different clades.

Hybridization in the course of adaptive radiation sets up a scenario where gene flow and selection toward local adaptive peaks may interact. This will often happen between diverging sister taxa but it may also happen between more distantly related taxa within a radiation. Especially in the latter case, gene flow may introduce new combinations of genes that have never before been segregating in one population and may facilitate adaption or renewed speciation in the recipient population. Thus, occasional introgressive gene exchange between nonsister species in adaptive radiations may be important for construction of new gene and trait combinations in rapidly radiating taxa (Meier et al. 2017, 2018), in some cases leading to hybrid speciation (Lamichhaney et al. 2018). Hybridization has been well documented in a number of classic adaptive radiations including Hawaiian silverswords (Carr 1987; Carlquist et al. 2003), Hawaiian *Bidens* (Knope et al. 2020), Darwin’s finches in the Galapagos (Lamichhaney et al. 2015), *Heliconius* butterflies (Heliconius Genome Consortium 2012), and African cichlid fish (Seehausen 2015). However, demonstrating admixture among radiating species and demonstrating its effects on further adaptive radiation are two different things and whether admixture among members of a radiation actually enhances further speciation within adaptive radiation (Carr 1987) can be difficult to test. Testing the syngameon hypothesis of adaptive radiation therefore requires combining population genomic, demographic and phenotypic analyses (Meier et al. 2018).

The hybrid swarm origin of adaptive radiation is different from the syngameon hypothesis of adaptive radiation in that the onset of adaptive radiation happens in a population that is of hybrid origin between potentially quite distantly related species. Admixture between such species—that have not themselves diverged from each other under divergent natural selection but may have long history of completely independent evolution—introduces a wide range of genetic variants into a single population that have never cosegregated within a population. Such admixture between divergent taxa has been implicated in establishing the radiation of Hawaiian silverswords (Barrier et al. 1999), *Rhagoletis* fruit flies (Feder et al. 2003), and several cichlid radiations (Irisarri et al. 2018; Meier et al. 2017). The hybrid swarm origin hypothesis for adaptive radiation makes predictions that are unconfounded by the fact that species in young radiations tend to hybridize. Its unique predictions are, first, that the most recent common ancestor of all members of a radiation is a population of hybrid origin between distinct species, and second, that new combinations of old alleles brought together by the hybridization event (i.e., that did not exist in either of the parental lineages alone) play important roles in speciation and adaptation during the radiation (Seehausen 2004). This combination of hypotheses receives its strongest support to date from work on the Lake Victoria Region superflock of cichlid fish, which originated from hybridization

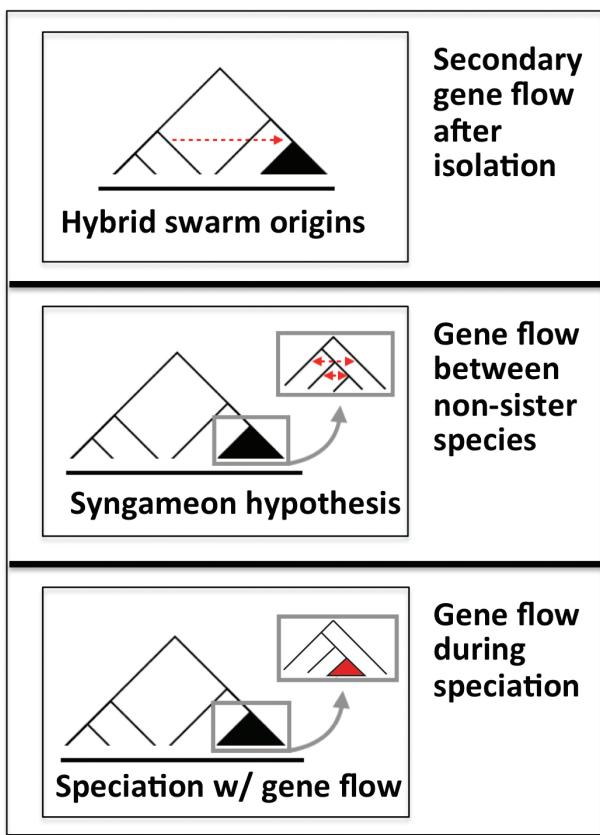

Figure 5. Gene flow, traditionally considered to hinder divergence between incipient species, can serve to infuse variability that may foster adaptive radiation. This can take place through (a) hybrid origins of entire radiating clades (“hybrid swarm origins”) wherein admixture between one or more divergent lineages happens prior to the onset of radiation, (b) via hybridization between nonsister species within adaptive radiations that facilitates further speciation (“syngameon hypothesis”) (Seehausen 2004), and (c) speciation with gene flow between sister species. It is important to distinguish between how admixture is achieved in order to assess its effects on the process of adaptive radiation (Brock and Wagner 2018). Both syngameon and hybrid swarm origins hypotheses have now been well documented in cichlid fish (Meier et al. 2017), and the importance of gene flow and the syngameon have been well demonstrated in *Heliconius* butterflies (Mallet 2005; Merrill et al. 2015), as well as many plants (Barrier et al. 1999; Friar et al. 2008), and are also found in many other lineages (Feder et al. 2003; Lamichhaney et al. 2018). Indeed, the processes may be common to many adaptive radiations. Moreover, there may be a “sweet spot” in which divergent lineages can admix or hybridize and give rise to variability that is key to adaptive radiation.

between ecologically similar *Astatotilapia/Thoracochromis* species from the Upper Nile region and the upper Congo river, lineages which have diverged for millions of years in geographical isolation and are not very different ecologically (Meier et al. 2017). It is possible that variation in propensity for hybridization may help explain why some lineages radiate adaptively while other similar lineages do not (Meier et al. 2019). In smaller radiations of other cichlids and pupfish, there also is evidence that introgression from distantly related species outside the lake may have triggered adaptive radiation (Richards and Martin 2017; Poelstra et al. 2018; Richards et al. 2018). As our ability to test for these patterns with genomic data mounts, explicit tests of this hypothesis should become more common.

To conclude, mechanisms for the separation of gene pools into species are clearly required for adaptive radiation (Figure 5). However, it appears that genetic admixture between species may sometimes facilitate adaptive radiation, likely in conjunction with ecological opportunity and spatially heterogeneous or ecologically multifarious selection. However, as genomic evidence for admixture in the history of adaptive radiations increases, there is a need to carefully distinguish between the genomic signatures of processes associated with the hybrid swarm origin mechanism versus the syngameon mechanism of adaptive radiation. There is now clear genomic evidence for mechanisms associated with both hypotheses. Furthermore, these processes are both distinct from the commonly discussed speciation-with-gene flow, and caution is needed to avoid confounding the genomic signatures of these processes. Because the genetic and phenotypic novelty generated by hybridization tends to increase with the age of lineages while genetic incompatibilities increasingly prevent admixture of lineages when they are too divergent, there may be an optimal degree of divergence between populations or species at which admixture might facilitate adaptive radiation (Stelkens et al. 2010; Comeault and Matute 2018). The critical timing of admixture likely depends on attributes of the lineage in question, highlighting the need for comparative studies (Marques et al. 2019).

Conclusions

The most important outcome from the current assessment is that adaptive radiation can proceed along multiple distinct evolutionary trajectories. We can only make progress in developing a synthetic understanding of adaptive radiation and speciation if we can distinguish apples from oranges and understand both commonalities and differences broadly across different radiations. For example, in lineages in which initial divergence is linked to divergent selection between different environments external to the radiation, repeated evolution of ecotypes is a common outcome, such as those associated with high- and low-elevation wolf spiders in the Galapagos (De Busschere et al. 2010), adaptation to wet and dry habitats in Hawaiian silverswords (Blonder et al. 2016), and benthic and limnetic crater lake cichlids (Kusche et al. 2014) (Figure 3). In contrast, lineages of lizards and spiders are known for the repeated evolution of co-occurring and interacting species belonging to distinct ecomorphs (Losos 2009; Gillespie et al. 2018); this pattern may often be associated with ecological and/or reproductive character displacement due to interactions between closely related lineages that occur in secondary contact after a period of divergence in allopatry (Figure 4). Likewise, to evaluate the role of admixture in adaptive radiation, we must distinguish signatures consistent with the syngameon hypothesis from those consistent with the hybrid swarm hypothesis, and both from signatures expected under speciation-with-gene flow between incipient species (Figure 5). Once we recognize similarities and differences in the processes underlying diversification across a wide-range of lineages, we can look at other aspects of the evolutionary process upon which adaptive radiations can shed light, most notably concepts of specialization, abundance, and equilibrium diversity, to name a few. We have now an unprecedented array of tools to genetically dissect phenotypes, refine phylogenetic relationships and demographic histories, and more accurately resolve the tempo and mode of divergence.

However, at the same time we must also appreciate that many different processes are likely to interact and synergistically increase

the biodiversity generated during adaptive radiation. Thus, while we may separate the factors driving specific aspects of species diversification, we must at the same time synthesize to fully comprehend the causal basis of adaptive radiations broadly. Moreover, in addition to elucidating how niches are filled, key questions remain concerning (i) how new or underutilized niches are created and (ii) whether and how adaptive radiation in one clade may reverberate throughout communities and ecosystems. Such cascading interactions (Brodersen et al. 2018) can potentially broadly influence biodiversity on multiple ecological scales. Given appropriate comparisons and a broad view of adaptive radiation, we have at our fingertips the ability to answer questions that have, until now, baffled our understanding of the diversification process. It is an exciting time for new and old investigators alike, as myriad research opportunities in adaptive radiation are now open and available to explore.

Glossary

- Adaptive radiation—evolutionary divergence of members of a single phylogenetic lineage into a variety of different adaptive forms (Futuyma 1998).
- Admixture—when individuals from two or more previously separated populations begin interbreeding resulting in the introduction of new genetic lineages into a population.
- Character displacement
 - Reproductive character displacement is the adaptive evolution of traits that minimize deleterious reproductive interactions between species; when arising from selection to avoid hybridization, it is the same as reinforcement.
 - Ecological character displacement
- Developmental plasticity—a developmental change in form or behavior caused by environmental conditions (West-Eberhard 2003).
- Divergent selection—natural or sexual selection that favors different phenotypes in different populations.
- Diversification—evolution of phenotypically and reproductively distinct species in a clade.
- Disruptive selection—natural or sexual selection that favors extreme over intermediate phenotypes within a single population (Rueffler et al. 2006).
- Ecological character displacement—the divergence of sympatric species to minimize ecological overlap.
- Ecological opportunity—the availability of ecologically accessible resources that may be evolutionarily exploited (Stroud and Losos 2016).
- Ecological speciation—the process by which barriers to gene flow evolve between populations as a result of ecologically based divergent selection (Schluter 2009).
- Enemy-free space or release—“ways of living that reduce or eliminate a species” vulnerability to one or more species of natural enemies’ including competitors (Jeffries and Lawton 1984).
- Evolvability—the capacity to generate heritable phenotypic variation (Stroud and Losos 2016).
- Hybrid swarm—a population of hybrids that has survived beyond the initial hybrid generation, with interbreeding between hybrid individuals and backcrossing with its parent types.
- Introgression—gene flow from one species into the gene pool of another.
- Key innovation—in evolution, any modification in structure or function that permits a lineage to exploit the environment in a more efficient or novel way and thereby creates ecological opportunity.
- Geographic separation terms:
 - Allopatry: Separated in space in such a way as to prevent the organisms from interacting during normal activity.
 - Sympatry: No spatial separation, allowing organisms to interact regularly during normal activity.
 - Syntopy: a special case of sympatry involving the joint occurrence of two species in the same habitat at the same time.
 - Mosaic allopatry: Separated in space in a mosaic manner, i.e. with no single clear boundary, but the separation still preventing the organisms from interacting during normal activity.
 - Microallopatry: Despite overlapping range, microallopatric taxa are still separated in space with interaction between taxa prevented because they occupy different ecological niches.
- Mutation-order speciation—different and incompatible mutations fix in different populations adapting to the same selective pressure (i.e. uniform selection, Mani and Clarke 1990). Mutations can arise stochastically in different order, allowing ‘mutation-order’ to serve as a stochastic driver of divergence (Nosil and Flaxman 2011).
- Nonadaptive radiation—lineage diversification with minimal ecological diversification, resulting in allopatric or parapatric (Rundell and Price 2009) and sometimes even sympatric taxa (Xu and Shaw 2020).
- Prezygotic barriers—anything that prevents mating and fertilization; postzygotic barriers—act after fertilization (zygote mortality, hybrid sterility)
- Priority Effects (Fukami et al. 2007; De Meester et al. 2016):
 - Ecological priority effect: the arrival order of species influences community dynamics and structure.
 - Genetic priority effect: an evolutionary priority effect whereby the arrival order of genotypes influences population genetic structure.
 - Evolution-mediated priority effect: the arrival order of genetic lineages or species and their evolution influences population genetic or community dynamics.
- Reinforcement—the evolution of traits that minimize hybridization between incipient species
- Reproductive isolation—factors involved in initial stages
 - Extrinsic: Fitness reduction in hybrids that is dependent on the environment and that is mediated by genotype–environment interactions.
 - Intrinsic: often due to genetic incompatibilities; these occur independent of the environment (for example, Bateson-Dobzhansky–Muller incompatibilities).
- Syngameon—Taxa that show long-term evidence of hybridization among multiple species (Lotsy 1925).
- Taxon cycle—sequential phases of expansion and contraction of the ranges of species, associated generally with shifts in ecological distribution. The important contribution of the taxon cycle to adaptive radiation is its emphasis on evolutionary and ecological interactions among colonizing and resident species, which influence their extinction dynamics and establish patterns (Ricklefs and Bermingham 2002b).

Acknowledgements

We would like to thank the AGA 2018 for sponsoring the symposium on the “Origins of Adaptive Radiation” held in Waimea, Hawaii, July 2018, and we thank all the participants at the meeting for lively and creative discussions. Particular thanks to Anjanette Baker for her outstanding efforts in allowing the symposium to run smoothly, and to Bill Murphy for his help with the manuscript. The manuscript was much improved by thoughtful and extensive suggestions from Egbert Leigh, George Roderick, and one anonymous reviewer.
